Carotid body inflammation and cardiorespiratory alterations in intermittent hypoxia

Rodrigo Del Rio, Esteban A. Moya, María J. Parga, Carlos Madrid and Rodrigo Iturriaga

ABSTRACT: Chronic intermittent hypoxia (CIH), a main feature of obstructive sleep apnoea (OSA), increases hypoxic ventilatory responses and elicits hypertension, partially attributed to an enhance carotid body (CB) responsiveness to hypoxia. As inflammation has been involved in CIH-induced hypertension and chemosensory potentiation, we tested whether ibuprofen may block CB chemosensory and cardiorespiratory alterations induced by CIH in a rat model of OSA.

We studied the effects of ibuprofen (40 mg kg⁻¹ day⁻¹) on immunohistochemical interleukin (IL)-1β and tumour necrosis factor (TNF)-α levels in the CB, the number of c-fos-positive neurons in the nucleus tractus solitarii (NTS), CB chemosensory and ventilatory responses to hypoxia, and arterial blood pressure in male rats either exposed for 21 days to 5% O₂ (12 episodes h⁻¹, 8 h·day⁻¹) or kept under sham condition.

CIH increased CB TNF-α and IL-1β and c-fos-positive neurons in the NTS, enhanced carotid chemosensory and ventilatory hypoxic responses, and produced hypertension. Ibuprofen prevented CB cytokine overexpression and CIH-induced increases in c-fos-positive neurons in the NTS, the enhanced hypoxic ventilatory responses and hypertension, but failed to impede the CB chemosensory potentiation.

Results suggest that pro-inflammatory cytokines may contribute to the CIH-induced cardiorespiratory alterations, acting at several levels of the hypoxic chemoreflex and cardiovascular control pathways.

KEYWORDS: Hypertension, hypoxia, inflammation, obstructive sleep apnoea

Obstructive sleep apnoea (OSA) syndrome, a rising worldwide health problem, is characterised by chronic intermittent hypoxia (CIH), which is considered the main risk factor for developing hypertension and other cardiovascular diseases [1–3]. It has been proposed that oxidative stress, inflammation and sympathetic activation are involved in OSA-induced hypertension [3–6]. A growing body of evidence suggests that CIH enhances carotid body (CB) chemosensory responses to hypoxia contributing to the OSA-induced hypertension [6–9]. Indeed, OSA patients and animals exposed to CIH show potentiated ventilatory, sympathetic and cardiorespiratory responses to acute hypoxia [6–10]. Furthermore, recordings of carotid chemosensory discharges in situ and in vitro have shown that CIH selectively increases basal chemosensory discharges in normoxia and potentiates the chemosensory responses to acute hypoxia in rats and cats [9, 11–13].

The repetitive episodes of hypoxia–reoxygenation during CIH exposure elicits oxidative stress due to the accumulation of reactive oxygen species (ROS), which are involved in the potentiation of the hypoxic CB chemosensory responses [9, 11, 13, 14] and in the pathological consequences observed in animals exposed to CIH, and in OSA patients [3–5, 8, 9, 13]. Recently, we found that ascorbic acid supplementation, which impedes the systemic and local CB oxidative stress in the rat exposed to CIH for 21 days, prevented enhanced CB chemosensory and ventilatory responses to hypoxia, as well as hypertension [13]. These observations support a main contribution for oxidative stress in the generation of the CB chemosensory potentiation.
and the cardiorespiratory alterations induced by CIH. Nevertheless, a direct effect of ROS in the CB oxygen process is still matter for debate. Indeed, the application of H$_2$O$_2$ does not produce CB chemosensory excitation [15, 16]. Moreover, modifications of ROS production in the CB do not modify the catecholaminergic secretory response to hypoxia, indicating a lack of a causal link between ROS levels and chemoreceptor activity [17]. Thus, it is likely that other molecules downstream of the ROS signals may mediate the enhancing effects of ROS on CB chemoreception under intermittent hypoxia. Among other molecules upregulated in the CB by CIH, such as endothelin (ET)-1 and inductible nitric oxide synthase [14, 18, 19], pro-inflammatory cytokines have been proposed as mediators of the CB chemosensory potentiation induced by CIH [9, 14]. Indeed, recently we found that CIH for 21 days increases the expression of tumour necrosis factor (TNF)-α and interleukin (IL)-1β in rat CB [9], molecules which are considered excitatory modulators of the CB oxygen chemoreception [20, 21].

The progression of the hypertension in OSA patients and animals exposed to CIH is also associated with increased levels of pro-inflammatory cytokines [1, 3, 5]. An increased ROS production induced by hypoxia–reoxygenation evokes the synthesis and secretion of pro-inflammatory cytokines [22]. Thus, we hypothesised that a treatment with an anti-inflammatory drug may prevent both the CB chemosensory potentiation and the cardiorespiratory alterations in rats exposed to CIH. Accordingly, we studied the effects of the nonsteroidal anti-inflammatory drug ibuprofen on the number c-fos-positive neurons in the NTS of rat CB to find out whether the upregulation of these cytokines was downstream of the ROS signalling pathways. As the nucleus of the tractus solitarii (NTS) plays a major role in the integration of baro- and chemosensory signals [23], and because of the fact that CIH increases the number of c-fos-positive neurons in the rat NTS, indicating changes in neuronal activity [24, 25], we also addressed the effects of ibuprofen on the number c-fos-positive neurons in the NTS of rats exposed to CIH.

**METHODS**

**Animals and exposure to intermittent hypoxia**

Experiments were performed on 40 adult male Sprague–Dawley rats, initially weighing 200 g. Rats were fed with standard chow diet ad libitum, and kept on a 12-h light/dark schedule (08.00 h–20.00 h). Animals were randomly assigned to CIH or to sham conditions. Researchers unaware of the identity of the treatment performed the physiological recordings and immunohistochemical studies. The experimental procedures were approved by the Bio-ethical Committee of the Biological Sciences Faculty, P. Universidad Católica de Chile, and were performed according to the National Institutes of Health guide for the care and use of laboratory animals.

Unrestrained, freely moving rats housed in individual chambers were either exposed to hypoxic cycles of 5% inspired O$_2$ for 20 s, followed by room air for 280 s, applied 12 times per hour, 8 h·day$^{-1}$ or were kept under sham condition for 21 days [13]. The O$_2$ level in the chambers was continuously monitored using an oxygen analyser (Ohmeda 5120; BOC Healthcare, Manchester, UK) and the CO$_2$ was maintained at a low level by continuous air extraction. Under the sham conditions, the hypoxic exposure was replaced by means of flushing an equal flow of compressed air into the chambers. The room temperature was kept at 23–25°C.

**Chronic subcutaneous ibuprofen treatment**

2 days before the beginning of CIH or sham exposures, animals were anaesthetised with 3% isofluorane in O$_2$, and osmotic minipumps (2ML4; Alzet Scientific Products, Chevy Chase, MD, USA) were implanted subcutaneously on the back. The pumps were filled with 400 mg ibuprofen in 2 mL NaCl 0.9%, to achieve a delivering concentration of ~40 mg·kg$^{-1}$·day$^{-1}$, at a rate of 2.5 μL·h$^{-1}$. Control animals were implanted with pumps containing NaCl 0.9%.

**Ascorbic acid treatment**

In separate experiments, ascorbic acid (1.25 g·L$^{-1}$) was administered through the drinking tap water from the first day of CIH exposure, as previously described [13]. The water solution was freshly prepared every day, and preserved in dark containers to avoid oxidation.

**Recording of physiological responses**

Acute experiments were performed in the morning of the day after the last day of the 21 days of CIH exposure. Rats were anaesthetised with sodium pentobarbitone (40 mg·kg$^{-1}$ i.p.), followed by additional doses when necessary to maintain a level of surgical anaesthesia (stage 3 plane 2). Rats were placed in supine position and the body temperature monitored by a rectal probe was maintained at 38.0±0.5°C with a heating pad. The trachea was cannulated for airflow recording, and connected to a pneumotachograph to obtain tidal volume (VT), respiratory frequency (fR), and minute ventilation (V'TE). One femoral artery was cannulated with a polyethylene tube, filled with 50 IU·mL$^{-1}$ of heparin solution for measuring arterial blood pressure with a transducer (Statham P23; Statham-Gould, Valley View, OH, USA). Cardiac frequency (fC) was measured from the ECG recordings. Physiological variables were acquired with an analogue–digital system (PowerLAB 8SP; ADInstruments, Bella Vista, Australia) and analysed with the Chart 7.2-Pro software. To assess the effects of CIH on the reactivity of the peripheral hypoxic chemoreflex, we measured ventilatory responses elicited by several isocapnic levels of oxygen tension (P$_{O2}$; 5–670 mmHg), maintained until the response was in a steady state (~10–20 s).

**Recording of carotid body chemosensory discharge**

At the end of the ventilatory physiological recordings, one carotid sinus nerve was dissected and placed on a pair of platinum electrodes, and covered with warm mineral oil. The neural signal was pre-amplified (Grass P511; Grass Instruments, Quincy, MA, USA), filtered (30 Hz–1 kHz) and fed to an electronic spike-amplitude discriminator, allowing the selection of action potentials of given amplitude above the noise to be counted with a frequency meter to measure the frequency of carotid chemosensory discharge, expressed in Hz. Carotid sinus barosensory fibres were eliminated by crushing...
the common carotid artery wall between the carotid sinus and the carotid body. The other carotid sinus nerve was cut to prevent vascular and ventilatory reflexes evoked by the activation of the CB. The chemosensory discharge was measured at several isocapnic levels of PO2 (5–670 mmHg).

**Immunohistochemistry for cytokines in the CB**

Quantitative immunohistochemistry was used to address the relative levels of TNF-α and IL-1β in the CB as previously described [13]. Anaesthetised rats were perfused intracardially with PBS at pH 7.4 for 10 min followed by buffered 4% paraformaldehyde (PFA; Sigma-Aldrich, Rockville, MD, USA). The carotid bifurcations with the CBs were dissected and post-fixed in the same fixative solutions for 12 h at 4°C. Samples were then dehydrated in ethanol, included in paraffin, cut into 5-μm sections and mounted on silanised slides. After deparaffinisation, samples were submitted to microwave-based antigen-retrieval protocol (700 W for 6 min in citrate buffer 1 M, pH 6.0). Samples were incubated with 0.3% H2O2 to inhibit endogenous peroxidase and then in normal horse serum blocking solution (Vectorstain Elite ABC Kit; Vector Lab). Slides were incubated with specific antibodies overnight at 4°C in humidity chambers for detection of TNF-α (sc-1350, 1:20, goat anti-TNF-α; Santa Cruz Biotechnology, Santa Cruz, CA, USA) and IL-1β (sc-7884, 1:100, rabbit anti-IL-1β; Santa Cruz Biotechnology). After rinsing slides in cold PBS, samples were incubated with secondary antibodies conjugated to biotin followed by a ready-to-use stabilised ABC reagent (Vectorstain Elite ABC Kit; Vector Lab, Burlingame, CA, USA), rinsed and incubated for 1 h in Vectastain ABC Elite kit (Vector Lab, Burlingame, CA, USA), and revealed at 37°C in a dark chamber with 3,3'-diaminobenzidine tetrahydrochloride (DAB; Sigma). To avoid false positives during DAB chromogen quantification, special attention was kept to prevent DAB signal saturation. Samples were counterstained with Harris haematoxylin and mounted with Entellan (Merck, Whitehouse Station, NJ, USA). Photomicrographs of the CB tissue were taken at ×100 with a CCD-camera coupled to an Olympus CX 31 microscope (Olympus Corp., Tokyo, Japan), digitised and analysed using a colour deconvolution algorithm with the ImageJ software (National Institutes of Health, Bethesda, MD, USA). The positive immunoreactive intensity, averaged from four CB fields (9,200 μm² each) was expressed as optical integrated intensity.

**Immunohistochemistry for c-fos expression in the NTS**

Anaesthetised rats were perfused through the left ventricle with 4% PFA in PBS (pH 7.4), and the brains were post-fixed in the same fixative for 2 h and transferred to 30% sucrose with 4% PFA in PBS (pH 7.4), and the brains were post-fixed in the same fixative for 2 h and transferred to 30% sucrose with 4% PFA in PBS (pH 7.4). Anaesthetised rats were perfused intracardially with PBS at pH 7.4 for 10 min followed by buffered 4% paraformaldehyde (PFA; Sigma-Aldrich, Rockville, MD, USA). The carotid bifurcations with the CBs were dissected and post-fixed in the same fixative solutions for 12 h at 4°C. Samples were then dehydrated in ethanol, included in paraffin, cut into 5-μm sections and mounted on silanised slides. After deparaffinisation, samples were submitted to microwave-based antigen-retrieval protocol (700 W for 6 min in citrate buffer 1 M, pH 6.0). Samples were incubated with 0.3% H2O2 to inhibit endogenous peroxidase and then in normal horse serum blocking solution (Vectorstain Elite ABC Kit; Vector Lab). Slides were incubated with specific antibodies overnight at 4°C in humidity chambers for detection of TNF-α (sc-1350, 1:20, goat anti-TNF-α; Santa Cruz Biotechnology, Santa Cruz, CA, USA) and IL-1β (sc-7884, 1:100, rabbit anti-IL-1β; Santa Cruz Biotechnology). After rinsing slides in cold PBS, samples were incubated with secondary antibodies conjugated to biotin followed by a ready-to-use stabilised ABC reagent (Vectorstain Elite ABC Kit; Vector Lab, Burlingame, CA, USA), rinsed and incubated for 1 h in Vectastain ABC Elite kit (Vector Lab, Burlingame, CA, USA), and revealed at 37°C in a dark chamber with 3,3'-diaminobenzidine tetrahydrochloride (DAB; Sigma). To avoid false positives during DAB chromogen quantification, special attention was kept to prevent DAB signal saturation. Samples were counterstained with Harris haematoxylin and mounted with Entellan (Merck, Whitehouse Station, NJ, USA). Photomicrographs of the CB tissue were taken at ×100 with a CCD-camera coupled to an Olympus CX 31 microscope (Olympus Corp., Tokyo, Japan), digitised and analysed using a colour deconvolution algorithm with the ImageJ software (National Institutes of Health, Bethesda, MD, USA). The positive immunoreactive intensity, averaged from four CB fields (9,200 μm² each) was expressed as optical integrated intensity.

**Statistical data analysis**

Data were expressed as mean ± SEM. Differences between more than three groups were assessed by one- or two-way ANOVA tests, followed by Newman–Keuls or Bonferroni post hoc comparisons.

**RESULTS**

The effect of CIH on fR, VT, Ve, systolic (Ps) and diastolic arterial pressure (Pd) and fC did not differ between any groups (p ≥ 0.05, one-way ANOVA). Exposure of rats to CIH for 21 days increased the mean arterial blood pressure due to a significant increase in both Ps and Pd as compared with sham rats (fig. 1 and table 1) (p ≤ 0.001 Newman–Keuls test after one-way ANOVA). Ibuprofen treatment for 21 days prevented the CIH-induced hypertension (fig. 1). We found that sham rats treated with ibuprofen showed a decrease in arterial blood pressure (table 1 and fig. 1). Nevertheless, the decrease in arterial blood pressure was not statistically different as related to the sham rats (p ≥ 0.05, Newman–Keuls test after one-way ANOVA).

Rats exposed to CIH showed higher reflex ventilatory responses to acute hypoxia as compared with sham, CIH+ibuprofen and sham+ibuprofen rats (fig. 2) (p ≤ 0.001, Newman–Keuls test}

Data are presented as mean ± SEM. Sham: control animals; CIH: rats exposed to chronic intermittent hypoxia; sham+IB: control rats that received ibuprofen; CIH+IB: rats treated with ibuprofen during the exposure to chronic intermittent hypoxia; VT: tidal volume; fR: respiratory frequency; Ps: systolic blood pressure; Pd: diastolic blood pressure; fC: cardiac frequency. *: p < 0.001, †: p < 0.05; Newman–Keuls test after one-way ANOVA.
after two-way ANOVA). Thus, treatment with ibuprofen prevented the potentiation of reflex ventilatory responses to acute hypoxia induced by CIH. On the contrary, the CIH-induced potentiation of the CB chemosensory response to acute hypoxia was not prevented by ibuprofen (fig. 3). The two-way ANOVA analysis showed that the overall CB chemosensory curve for PO2 was not different between the CIH and CIH+ibuprofen rats (p > 0.05). Ibuprofen treatment did not modify the carotid chemosensory response in the sham rats.

We found significantly increased levels of TNF-α immunoreactivity (TNF-α-ir) and IL-1β immunoreactivity (IL-1β-ir) in the CBs from rats exposed to CIH for 21 days, which was prevented by ibuprofen treatment (fig. 4a and b). As is shown in fig. 4c and d, ibuprofen reduced the increased TNF-α-ir and IL-1β-ir by 70% and 40%, respectively, as compared with the increased optical integrated intensity measured in CIH-treated rats. We did not find differences between the TNF-α-ir and IL-1β-ir levels in the CBs from sham rats treated either with or without ibuprofen (p > 0.05) (online supplementary fig. S1). The increased levels of TNF-α-ir and IL-1β-ir in the rat CB exposed to CIH depended on the oxidative stress, as ascorbic acid treatment during the hypoxia protocol for 21 days reduced the enhanced levels of TNF-α-ir and IL-1β-ir in the CB from rats exposed to CIH (fig. 5). We found that CIH increased the number of c-fos-positive neurons in the caudal portion of the rat NTS, while ibuprofen treatment attenuated the number of positive neurons (fig. 6). Ibuprofen itself did not change the expression of c-fos. Indeed, we did not find changes in the number of c-fos-positive neurons in the NTS from sham rats treated either with or without ibuprofen (p > 0.05) (online supplementary fig. S2).

**DISCUSSION**

The main findings of this study showed that ibuprofen, which prevented the CIH-increased TNF-α and IL-1β in the CBs and the number of c-fos-positive neurons in the caudal NTS, failed to impede the potentiation of the carotid chemosensory responses to acute hypoxia, but effectively prevented the potentiation of the chemoreflex ventilatory responses to hypoxia as well as hypertension. Thus, the CIH-induced potentiation of the CB chemosensory responses does not depend on the increased TNF-α and IL-1β levels in the CB, although the increased level of these pro-inflammatory cytokines plays an essential role in the generation of the cardiorespiratory alterations induced by CIH, probably acting at different levels on the hypoxic ventilatory reflex arc and cardiovascular control pathways. In addition, our results showed that ascorbic acid, which prevents the CIH-induced potentiation of the chemosensory responses to hypoxia

**FIGURE 1.** Ibuprofen (IB) treatment for 21 days prevented chronic intermittent hypoxia (CIH)-induced hypertension in rats. and the local oxidative stress in the rat CB [13], blocked the increased TNF-α and IL-1β in the rat CB, indicating that the increased cytokines levels in the CB are secondary to oxidative stress. The inhibitory effect of ibuprofen on cytokine accumulation induced by CIH in the CB is consistent with its known anti-inflammatory effect. Although ibuprofen is considered to be a nonselective inhibitor of cyclo-oxygenases 1 and 2, it is known that ibuprofen inhibits the nuclear translocation of the transcription factor, nuclear factor (NF)-κB, which mediates TNF-α and IL-1β production [26].

**Cytokines and CB chemosensory potentiation**

The enhanced production of ROS induced by hypoxic-reoxygenation cycles evokes the expression of genes and the synthesis of pro-inflammatory cytokines, mediated by the activation of transcription factors such as NF-κB and hypoxia inducible factor (HIF)-1α [23]. In response to oxidative stress, HIF-1α induces the expression of several proteins, including ET-1, which transiently increased in rat CB exposed to CIH [13]; however, oxidative stress also enhances the expression of pro-inflammatory cytokines, such as IL-1β and TNF-α, in the CB, suggesting that chemoreceptor cells can synthesise and release cytokines. Inflammatory processes have been involved in the enhanced reactivity of the CB chemosensory response to hypoxia in rats exposed to sustained hypoxia [27]. Indeed, Lam et al. [20] found that sustained hypobaric hypoxia recruits macrophages to the rat CB, increases the mRNA expression of IL-1β and TNF-α, and interleukin 1 receptor type I (IL-1R1) and

tumour necrosis factor receptor type I (TNF-R1) receptors. Liu et al. [21] found that the concurrent administration to rats exposed to sustained hypoxia of ibuprofen and dexamethasone reduced the potentiated CB chemosensory response to hypoxia, blocked the immune cell invasion and reduced the cytokine RNA expression. Intermittent hypoxia also produces a progressive increase of the TNF-α and IL-1β in the rat CB, but the CIH-induced increases of TNF-α and IL-1β-ir was not associated with CB tissue invasion of immune cell or increased plasma levels, suggesting that CIH augmented the local production of cytokines in the CB [14]. Present results showed that the CB chemosensory potentiation to hypoxia induced by CIH was not prevented by ibuprofen, while the increased levels of IL-1β and TNF-α in the CB were abolished by the anti-inflammatory treatment. Thus, our results suggest that the mechanisms underlying the hypoxic CB chemosensory potentiation induced by sustained and intermittent hypoxia are different.

Cytokines and cardiorespiratory alterations induced by intermittent hypoxia

The progression of the hypertension in OSA patients and animals exposed to CIH is associated with increased levels of pro-inflammatory cytokines [1, 2, 5]. Our results strongly suggest that pro-inflammatory cytokines contribute to the
CIH-induced cardiorespiratory alterations acting at different levels of the hypoxic chemoreflex and cardiovascular control pathways. Pupa et al. [28] reported that ibuprofen treatment blocked the increased ventilatory response to hypoxia and the increased IL-1 and IL-6 protein levels in the brainstem of rats exposed to chronic hypoxia, supporting the proposal that ibuprofen blocks inflammatory processes in the central nervous system (CNS), which contributed to the ventilatory acclimatization to sustained hypoxia. Present results showed a clear dissociation of the effects of ibuprofen on the CB potentiated chemosensory responses to hypoxia and to the reflex ventilatory response to hypoxia as well as on the hypertension induced by CIH. Thus, actions of cytokines on the arterial blood pressure and ventilatory reflex responses to hypoxia in rats exposed to CIH may occur in multiple sites, including the NTS and CNS. Nevertheless, we cannot rule out if the persistent CB chemosensory potentiation in rats exposed to CIH and treated with ibuprofen would be detrimental to cardiorespiratory function under long-term exposure to intermittent hypoxia. Future studies addressing the contribution of the CB chemosensory potentiation to cardiovascular and ventilatory alterations induced by long-term exposures to CIH are needed.

The available evidence suggests that the cardiorespiratory alterations induced by CIH originate from the enhanced CB chemosensory responsiveness to hypoxia [6–9] signals that are transmitted to the NTS, where the respiratory gas and blood pressure sensory signals are primarily integrated. Kline [23] found evidence that CIH increased postsynaptic neuron activity in the rat NTS, elicited by an augmented afferent sensory input and enhanced spontaneous synaptic discharge. The idea that CIH increases neural activity in the NTS is also supported by previous studies showing that c-fos immunoreactivity, a marker for neural activation, increased in the rat NTS following CIH [24, 25]. Moreover, it has been proposed that inflammation in the NTS contributes to the neurogenic hypertension [26]. Waki et al. [30] found that abnormal gene expression of pro-inflammatory molecules, such as the junctional adhesion molecule 1, are highly expressed in the NTS of spontaneously hypertensive rats and elicit leukocyte accumulation within the vasculature in the NTS. Accordingly, they proposed that cytokines and chemokines might contribute to elevate the arterial pressure by increasing the neuronal activity in the NTS of spontaneous hypertensive rats [30]. Our results, showing that ibuprofen reduced the c-fos immunoreactivity in neurons of the caudal NTS, support a novel role for inflammation in hypertension induced by CIH.

**Clinical perspectives**

OSA syndrome is recognized as an independent risk factor for cardiovascular diseases [1, 2]. Indeed, >50% of OSA patients develop diurnal hypertension attributed to oxidative stress and inflammation [1–5]. The gold standard therapy for patients with severe OSA is the application of continuous positive airway pressure (CPAP) during sleep, which reduces the production of ROS and inflammatory molecules and reverses hypertension [1, 2]. However, there are no specific treatments, based on antioxidant or anti-inflammatory drugs, for OSA patients presenting with low adherence to CPAP as well as patients with mild or moderate OSA [1, 2]. Thus, a potential therapeutic use of antioxidants and/or anti-inflammatory drugs in OSA deserves further attention. The present results show that ibuprofen treatment prevented the cardiorespiratory alterations induced by CIH, suggesting that anti-inflammatory drugs may potentially be used to ameliorate the hypertension associated with OSA. However, the prolonged use of anti-inflammatory drugs, including ibuprofen, may have some risk. Indeed, nonsteroidal anti-inflammatory drugs may increase the risk of cardiovascular thrombotic events, myocardial infarction and stroke, and the risk of gastrointestinal bleeding and ulceration [31]. In addition, prolonged use of ibuprofen may lead to onset of a new hypertension or worsening of a pre-existing hypertension [31]. Our results showed that the CIH-induced overexpression of IL-1β and TNF-α in the CB is
mediated by ROS and prevented by ascorbic acid, indicating that the increased cytokine levels are secondary to the oxidative stress. Studies performed in rats exposed to CIH have shown that antioxidant treatment prevents the hypertension [13, 32, 33]. Indeed, we recently reported that CIH increased plasma lipid peroxidation and 3-nitrotyrosine formation in rat CB, enhanced the CB chemosensory and ventilatory responses to hypoxia and produced hypertension [13]. Ascorbic acid treatment prevented the systemic and local CB oxidative stress, the potentiated chemosensory and ventilatory responses to hypoxia as well as the hypertension [13]. Thus, our results support a plausible therapeutic use of antioxidants and anti-inflammatory drugs in OSA patients. Antioxidants seem to be a better choice than anti-inflammatory drugs for the treatment of the OSA-induced hypertension, but anti-inflammatory drugs, such as ibuprofen, used with precaution and in low doses may also be beneficial. Based on the current available information, a long-term combined treatment of antioxidants and anti-inflammatory drugs needs further studies in animal models before being tested in clinical trials.

In summary, the present results suggest that the mechanisms underlying the upregulation of pro-inflammatory cytokines in the CB induced by CIH are linked to oxidative stress, as well as the enhanced CB chemosensory responsiveness to hypoxia. However, the CIH-induced potentiation of CB chemosensory responses to acute hypoxia does not depend on the increased TNF-α and IL-1β levels. Nevertheless, pro-inflammatory cytokines may contribute to the potentiation of hypoxic ventilatory chemoreflex responses to hypoxia and the progression of the hypertension induced by CIH. This suggests that multiple mechanisms may be involved in the cardiorespiratory alterations induced by CIH.
